ABSTRACT

We propose a tuning-free Bayesian approach to learn a set of sparse graphical models, in which adjacent graphs share similar structures. This model can be applied to estimating dynamic networks that evolve smoothly with regard to a covariate (e.g., time). Specifically, a novel structured spike and slab prior is constructed. This prior allows time-varying sparsity pattern by smoothing the spike probabilities across time using a Gauss-Markov chain. An efficient variational Bayes (VB) algorithm is then derived to learn the model, and is compared to related frequentist methods in the literature. We further extend the proposed mechanism to learn graphical models for multivariate time series in frequency domain. As an example, we analyze scalp electroencephalograms (EEG) recordings of patients at early stages of Alzheimer disease (AD), and quantify the loss of synchrony in comparison with control subjects.

Index Terms— Dynamic graphical models, structure, sparse Bayesian learning, time series

1. INTRODUCTION

The recent decades have witnessed a rapid development of graphical models, since they provide a refined language to describe complicated systems and further facilitate the derivation of efficient learning and inference algorithms [1]. While an extensive literature revolves around learning sparse graphical models from independent and identically distributed (i.i.d.) data (see [2, 3] and references therein), less research has been conducted on graphical models for observations drawn from a distribution that varies with a covariate (e.g. time or space).\(^1\) For instance, during epileptic seizures, functional brain networks are shown to evolve across time through a sequence of distinct topologies [4]. Estimating such networks can show how the dysrhythmia of the brain propagates and may help the treatment of epilepsy.

Existing works on learning time-varying networks can be categorized into three groups. The first one [5]-[8] considers the temporal dependence by smoothing the sufficient statistics across time using kernels. Given the temporally dependent sufficient statistics, the sparse graphical models are then estimated individually at each time point. The estimation problem can be solved by maximizing the likelihood with an $\ell_1$ penalty on the graph sparsity. However, such methods are only applicable in the settings where graphs continuously and smoothly evolve over time [9], whereas in practice the smoothness assumption cannot be broken at certain time points, such as the onset of seizure in the above example. Moreover, unexpected variability may arise between two adjacent networks since each network are estimated independently [10]. To mitigate these issues, the second group of dynamic network models [9, 11, 12] capture the temporal dependence by enforcing $\ell_1$ or $\ell_2$ norm constraints on the difference of two consecutive graphs. The resulting problem is usually convex, and can be solved by the alternating directions method of multipliers (ADMM). Finally, the third group combines both two aforementioned approaches [10, 13].

Unfortunately, the dynamic graphical models inferred by all three methods are sensitive to the tuning parameters, including the kernel bandwidth and the penalty parameters. Typical data-driven methods for selecting these parameters are cross validation (CV) and Akaike information criterion (AIC) [10]. However, heavy computational burden comes along with these methods; the learning algorithm needs to be run once for every possible value of the parameters in a predefined candidate set (which may be large) before the one associated with the largest AIC (or CV) score is chosen. Moreover, it has been demonstrated in [14] that neither CV nor AIC yields satisfying results for graphical model selection.

In this paper, we take a Bayesian approach to construct time-varying graphical models. The major benefit of the proposed algorithm is that all parameters can be estimated in an automatic manner from the data without tuning. In particular, we focus on Gaussian graphical models that characterize the conditional independence (i.e., absence of edges) by zero entries in the precision (inverse covariance) matrix. As a result, our objective is to infer the time-varying precision matrix. To this end, we propose a novel structured spike and slab prior. Specifically, each off-diagonal entry of the precision matrix can be factorized as the product of a Bernoulli and a Gaussian distributed variable, and these two variables are further coupled across time via Gauss-Markov chains (i.e.,

---

\(^1\)To provide a more readable presentation, we assume the covariate is time in this paper unless specified otherwise.
thin-membrane models [15]). We then develop an efficient VB algorithm to learn the model. Numerical results show that when compared with the frequentist method [11–12], the proposed method achieves better performance in terms of estimation accuracy with significantly less amount of computational time.

Interestingly, the proposed model can be directly applied to infer graphical models for multiple time series in frequency domain [16]. As an illustration, we apply the proposed model to multi-channel EEG signals of AD patients and healthy control subjects; we demonstrate that the graphical models inferred from the AD EEG signals are more sparse than those for healthy control subjects. Note that this effect is not always easily detectable, especially for patients in the pre-symptomatic phase. Thus, the proposed model may offer another useful tool for early detection of AD.

This paper is structured as follows. We first present our Bayesian model in Section 2, and then derive the VB algorithm in Section 3. In Section 4, we show the numerical results for both synthetic and real data. Finally, we close this paper with conclusions in Section 5.

2. DYNAMIC GRAPHICAL MODELS

In this section, we first introduce the proposed structured spike and slab prior, and subsequently construct the Bayesian model for time-varying graphical models. Finally, we explain how to exploit the proposed model to infer graphical models for stationary time series in frequency domain.

2.1. Structured Spike and Slab Prior

Suppose that $K_{ij}^{1:T}$ is off-diagonal entry $(i, j)$ of the $P \times P$ precision matrix $K$ with time from 1 to $T$. A spike and slab prior on $K_{ij}^{t}$ can be defined as [17]:

$$K_{ij}^{t} \sim \eta_{ij}^{t}N(\mu_{ij}^{t}, \nu_{ij}^{t}) + (1 - \eta_{ij}^{t})\delta_{0},$$

where $N(\mu_{ij}^{t}, \nu_{ij}^{t})$ is a Gaussian distribution with mean $\mu_{ij}^{t}$ and variance $\nu_{ij}^{t}$, $\delta_{0}$ is a Kronecker delta function, and $\eta_{ij}^{t} \in [0, 1]$ determines probability of $K_{ij}^{t} = 0$ (i.e., the spike probability). By decreasing $\eta_{ij}^{t}$ to 0, this prior would shrink $K_{ij}^{t}$ to 0, thus encouraging sparsity in $K$. The above expression can also be equivalently written as [18]:

$$K_{ij}^{t} = s_{ij}^{t}J_{ij}^{t},$$
$$J_{ij}^{t} \sim N(\mu_{ij}^{t}, \nu_{ij}^{t}),$$
$$s_{ij}^{t} \sim \text{Ber}(\eta_{ij}^{t}),$$

where $\text{Ber}(\eta_{ij}^{t})$ is a Bernoulli distribution with successful probability $\eta_{ij}^{t}$. To obtain $K^{t}$ that changes smoothly with $t$, we need to impose smoothness priors on both $s_{ij}^{t}$ and $J_{ij}^{t}$. First, let us focus on $s_{ij}^{t}$. One tempting approach is to assume $s_{ij}^{1:T}$ forms a binary Markov chain as in [18, 19]. However, as pointed out in [20], the resulting hidden Markov model (HMM) may induce unrealistically rapid switching between states. This problem can be eliminated by introducing a self-transition bias, giving rise to a sticky HMM [20]. Unfortunately, VB learning of the sticky HMM is prone to local maxima [21]. Instead of using binary Markov chains, Ren et al. [21] assume that $\eta_{ij}^{t} = g(\beta_{ij}^{t})$, where $g(\cdot)$ is the standard logistic function, and smoothen $\beta_{ij}^{t}$ across $t$ based on kernels. Although this method is amenable to the VB framework, the bandwidth of the kernels can only be estimated via Monte Carlo methods, thus slowing down the entire learning process. An alternative approach is proposed in [22], in which $\beta_{ij}^{t}$ is drawn from a Gaussian process and $g(\cdot)$ is the standard Gaussian cumulative distribution function. The parameters of the Gaussian process, however, have to be defined in advance; otherwise the computational cost of learning these parameters is $O(T^{3})$. Here, we specify $g(\cdot)$ to be the standard logistic function due to its utility in the VB framework [21]. We further assume $\beta_{ij}^{t}$ forms a Gauss-Markov chain, in particular, a thin-membrane model [15]. The resulting prior on $s_{ij}^{t}$ can be expressed as:

$$p(s_{ij}^{t} | \beta_{ij}^{t}) = \text{Ber}(s_{ij}^{t}; g(\beta_{ij}^{t})),$$
$$g(\beta_{ij}^{t}) = \frac{1}{1 + \exp(-\beta_{ij}^{t})},$$

$$p(\beta_{ij}^{1:T}) \propto \lambda^{\frac{T+1}{2}} \exp\left(-\frac{\lambda}{2} \sum_{t=2}^{T} (\beta_{ij}^{t} - \beta_{ij}^{t-1})^{2}\right),$$

where $\lambda$ is the smoothness parameter controlling the smoothness of $\beta_{ij}^{t}$ across $t$. We further impose a conjugate Gamma prior on $\lambda$:

$$p(\lambda) = \text{Gamma}(\lambda; a_{0}, b_{0}) \propto \lambda^{a_{0} - 1} \exp(-b_{0}\lambda).$$

The parameters $a_{0}$ and $b_{0}$ are set to be small (e.g., $a_{0} = b_{0} = 10^{-10}$) such that the prior is non-informative. As $\lambda$ increases, the thin-membrane model reduces the difference between consecutive $\beta_{ij}^{t}$ and $\beta_{ij}^{t-1}$, and the resulting prior favors that $s_{ij}^{t} = s_{ij}^{t-1}$. Similarly, to promote the smooth variation of $J_{ij}^{t}$ across $t$, we impose a thin-membrane prior with smoothness parameter $\gamma$ on $J_{ij}^{t}$, and a Gamma prior $\text{Gamma}(c_{0}, d_{0})$ on $\gamma$.

2.2. Time-Varying Graphical Models

Let $x_{i}^{1:T}$ denote the observations of the Gaussian graphical models from 1 to $T$. Then,

$$p(x_{i}^{1:T} | K^{t}) \propto \det(K^{t})^{\frac{1}{2}} \exp\left(-\frac{1}{2} x^{t}K^{t}x^{t}\right),$$

where $x^{t}$ is the (conjugate) transpose of $x^{t}$. In our model, to facilitate variational inference, we further relax the equality constraint in Eq. (2) as a Gaussian distribution:

$$p(K_{ij}^{t} | s_{ij}^{t}, J_{ij}^{t}, \alpha) \propto \sqrt{\alpha} \exp\left(-\frac{\alpha}{2} (K_{ij}^{t} - s_{ij}^{t}J_{ij}^{t})^{2}\right).$$

This resembles the Lagrangian multiplier in the frequentist methods [9, 12, 10]. As the learning algorithm proceeds, $\alpha$ will take a very large value, and the above Gaussian distribution degenerates to a Kronecker delta function $\delta_{0}(K_{ij}^{t} - s_{ij}^{t}J_{ij}^{t})$. Note that diagonal elements $K_{ii}^{t}$ in $K^{t}$ also follow
the above distribution, in which $s_{ij}^t$ is set to be 1 for all $t$. As before, a conjugate Gamma prior $\text{Gamma}(\alpha, \gamma)$ is imposed on $\alpha$. In summary, the overall Bayesian model can be factorized as:

$$p(x_1^T, K_1^T, J^1, s_k^1, \beta_1, \alpha, \gamma, \lambda)$$

$$= p(\alpha) p(\lambda) p(\gamma) \prod_{t=1}^{T} p(x^t | K^t) \prod_{i=1}^{P} \prod_{j=1}^{P} p(K_{ij}^t | s_{ij}^t, J_{ij}^t, \alpha)$$

$$\cdot p(s_{ij}^t | \beta_{ij}^t) \prod_{i=1}^{P} \prod_{j=1}^{P} \prod_{t=2}^{T} p(\beta_{ij}^t | s_{ij}^{t-1}, \ldots, s_{ij}^1, \lambda) p(\lambda | J_{ij}^{t-1}, \ldots, J_{ij}^1, \gamma).$$

The graphical model representation of the proposed model is shown in Fig 1.

### 2.3. Graphical Models for Time Series

In this section, we discuss how to exploit the proposed model to learn interactions among $P$ univariate stationary Gaussian processes (i.e., time series) $x_{1:p}$. A graphical model $G = (V, E)$ for $x^t$ can be constructed by letting an edge $(i,j) \notin E$ denote that the two entire time series $x_{1:T}^i$ and $x_{1:T}^j$ are conditionally independent given the remaining collection of time series $x_{1:T}^{V \setminus \{i,j\}}$, where $V, i, j$ denotes all nodes in $V$ except $i$ and $j$, that is [23]:

$$\text{cov}(x^t_i, x^{t+\tau}_{1:T} | x_{1:T}^{V \setminus \{i,j\}}) = 0, \ \forall \tau.$$

(10)

In other words, the lagged conditional covariance equals 0 for all time lag $\tau$. On the other hand, the conditional dependence can also be defined in frequency domain of the time series. Concretely, we first define the spectral density matrix as the Fourier transform of the lagged covariance matrix $\text{cov}(x^t, x^{t+\tau})$:

$$S^\omega = \sum_{\tau} \text{cov}(x^t, x^{t+\tau}) \exp(-i\omega \tau),$$

(11)

for $\omega \in [0, 2\pi]$. Let $K^\omega = (S^\omega)^{-1}$, the conditional independence between $x_i$ and $x_j$ holds if and only if [16, 23]

$$K_{ij}^\omega = 0, \ \forall \omega.$$  

(12)

This suggests that one common zero entry in the inverse spectral density matrices across a certain frequency band is equivalent to the conditional independence between the corresponding two time series in this frequency band. Therefore, for a multivariate time series, we aim to infer the inverse spectral density matrices $K^\omega$.

Here, we follow the state-of-the-art Whittle approximation framework [24]: suppose that $f_{i:p}^t$ is the discrete Fourier transform of $x_{1:T}^i$ at frequency $\omega$, then $f_{i:p}^t$ are independent complex Gaussian random variables with mean zero and precision matrix given by the inverse spectral density matrix $K^\omega$ at the same frequency. As a result, we can learn $K^\omega$ that changes smoothly with $\omega$ from $f^\omega$ using the proposed model in Section 2.2.

In this scenario, the covariate is the frequency $\omega$. Note that the proposed model is not directly applicable in time domain, since the assumption that $x^1$ and $x^{T-1}$ are conditionally independent given $K^T$ and $K^{T-1}$ is not satisfied for time series. Instead, in the settings of Whittle approximation [24], Fourier coefficients $f^\omega$ at different frequencies are conditionally independent given $K^\omega$.

### 3. VARIATIONAL BAYES LEARNING

In this section, we derive a mean field VB algorithm to learn the above Bayesian model (cf. Section 2.2). The VB algorithm seeks to approximate the intractable posterior distribution $p(\theta | x_{1:T}^i)$ with a tractable variational distribution $q(\theta)$ by minimizing the KL divergence between these two distributions $\text{KL}(q(p)) = \int q\log(q/p)$, where $\theta = \{K_{1:T}, J^1, s_k^1, \beta_1, \alpha, \gamma, \lambda\}$. This is equivalent to maximizing a lower bound of the data evidence. Concretely, we factorize the variational distribution as:

$$q(\theta) = q(\alpha)q(\lambda)q(\gamma) \prod_{i} \prod_{j} q(J_{ij}^{T})q(\beta_{ij}^{T}) \prod_{t} q(K_{ij}^t)q(s_{ij}^t).$$

The VB update rule can be then derived as follows. For the precision matrices $K^t$,

$$q(K^t) \propto \exp \left( \langle \log p(x^t | K^t) \rangle + \langle \log p(K^t | J^t, s^t, \alpha) \rangle \right)$$

$$\propto \exp \left( \frac{1}{2} \log \det K^t - \frac{1}{2} x^T K^t x^t - \frac{1}{2} \langle \|K^t - s^t \odot J^t\|_2^2 \rangle \right),$$

(13)

where $\langle \cdot \rangle$ denotes expectation, $\| \cdot \|_2$ denotes $\ell_2$ norm, and $\odot$ is a Hadamard product. Due to the non-conjugacy between $p(x^t | K^t)$ and $p(K^t | J^t, s^t, \alpha)$, it is intractable to compute the normalization constant of the above expression. Instead, we specify $q(K^t)$ as a product of independent Gaussian distributions $\prod_{i} \prod_{j} q(K_{ij}^t)$, whose mean $[\mu_{ij}]_{ij}$ and variance $[\nu_{ij}^2]_{ij}$ can be determined by Laplace approximation [25]. Specifically, equating to 0 the gradient of the exponential part in (13)
Algorithm 1 VB Learning of Time-Varying Graphical Models

Input: $x^{1:T}$;  
Output: $q(K_{ij}^t), q(s^{1:T})$;  
Initialize the variational parameters and iteration number $\kappa = 1$;  
Repeat
1. Update $q(K_{ij}^t) = N(\mu_{K_{ij}^t}^t, [\nu_{K_{ij}^t}^t], [\nu_{K_{ij}^t}^t])$:  
   1.1. $VDV' = \frac{1}{2}x^tx' - \langle \alpha \rangle s^t \odot J'$;  
   1.2. $D_{ii} = -D_{ii} + \sqrt{D_{ii}^2 + 2\langle \alpha \rangle} / 2\langle \alpha \rangle$;  
   1.3. $\mu_{K_{ij}^t}^t = V D V'$;  
   1.4. $\nu_{K_{ij}^t}^t = \frac{1}{2} \text{diag}(\mu_{K_{ij}^t}^{-1}) \text{diag}(\mu_{K_{ij}^t}^{-1})' + \langle \alpha \rangle$.

2. Update $q(s_{ij}^t) = \text{Ber}(s_{ij}^t; \tilde{\nu}_{ij}^t)$:
   2.1. $\tilde{\nu}_{ij}^t = g((\beta_{ij}^t) - \langle \alpha \rangle)(J_{ij}^t - 2(K_{ij}^t)(J_{ij}^t))$.

3. Update $q(\beta_{ij}^t)$:
   3.1. For $t = 1$ or $T$, $\phi(\beta_{ij}^t) \propto \exp(-h(\zeta_{ij}^t, \phi(\beta_{ij}^t)), ((s_{ij}^t) - 0.5))\beta_{ij}^t$.
   3.2. For $2 < t < T - 1$, $\phi(\beta_{ij}^t) \propto \exp(-h(\zeta_{ij}^t, \phi(\beta_{ij}^t)), ((s_{ij}^t) - 0.5))\beta_{ij}^t$.
   3.3. $\phi(\beta_{ij}^t, \beta_{ij}^{t-1}) \propto \exp(-\langle \alpha \rangle\beta_{ij}^{t-1})$.
   3.4. Compute mean $[\mu_{ij}^t]$ and variance $[\nu_{ij}^t]$ via belief propagation in the Gaussian Markov chain with unary potential $\phi(\beta_{ij}^t)$ and pairwise potential $\phi(\beta_{ij}^t, \beta_{ij}^{t-1})$.

4. Update $\zeta_{ij}^t = \sqrt{[\mu_{ij}^t]^2 + [\nu_{ij}^t]}$.
5. Update $q(J_{ij}^{1:T})$ in a similar manner as $q(\beta_{ij}^{1:T})$.
6. Update $q(\alpha), q(\lambda)$, and $q(\gamma)$.

Until convergence criterion is met.

w.r.t. $K_{ij}^t$ yields an equation of the mean matrix $\mu_{K_{ij}^t}^t$:  
\[
\frac{1}{2} \mu_{K_{ij}^t}^{-1} - \langle \alpha \rangle \mu_{K_{ij}^t} = \frac{1}{2} x^t x' - \langle \alpha \rangle (s^t) \odot (J') .
\]  (14)

Letting $VDV'$ denote the eigendecomposition of $\frac{1}{2} x^t x' - \langle \alpha \rangle (s^t) \odot (J')$, the solution of the above equation is given by $\mu_{K_{ij}^t} = V D V'$, where $D$ is the diagonal eigenvalue matrix with
\[
\tilde{D}_{ii} = -D_{ii} + \sqrt{D_{ii}^2 + 2\langle \alpha \rangle} / 2\langle \alpha \rangle .
\]  (15)

It follows from (15) that $\tilde{D}_{ii}$ is guaranteed to be positive, and therefore, $\mu_{K_{ij}^t}$ is always positive definite during the inference process. On the other hand, the variance of $q(K_{ij}^t)$ is given by the negative Hessian at $[\mu_{K_{ij}^t}]$, that is,
\[
\nu_{K_{ij}^t} = \frac{1}{2} \text{diag}(\mu_{K_{ij}^t}^{-1}) \text{diag}(\mu_{K_{ij}^t}^{-1})' + \langle \alpha \rangle ,
\]  (16)

where $\text{diag}(\cdot)$ is the diagonal of a matrix.

Next, we turn our attention to the update rule of $\beta_{ij}^t$. Its likelihood involves the logistic function, which spoils the conjugate-exponential structure. We overcome this limitation by utilizing a variational lower bound for $g(\beta_{ij}^t)$ based on bounding log convex functions [26]:
\[
g(\beta_{ij}^t) \geq g(\phi(\beta_{ij}^t)) \exp \left( \frac{\beta_{ij}^t - \zeta_{ij}^t}{2} - h(\zeta_{ij}^t) (\beta_{ij}^t)^2 - \zeta_{ij}^t \right),
\]

where $h(\zeta_{ij}^t) = \tanh(\zeta_{ij}^t/2)/(4\zeta_{ij}^t)$, and $\zeta_{ij}^t$ is a variational parameter to be estimated. The bound is exact at $\zeta_{ij}^t = \pm \beta_{ij}^t$. Given $\zeta_{ij}^t$, the Gaussian prior on $\beta_{ij}^t$ is now conjugate to the likelihood of $\beta_{ij}^t$, and the mean $[\mu_{ij}^t]$ and variance $[\nu_{ij}^t]$ of $q(\beta_{ij}^t)$ can be obtained via belief propagation in the Gaussian Markov chain. After obtaining $q(\beta_{ij}^t)$, the variational parameter $\zeta_{ij}^t$ can be updated as:
\[
\zeta_{ij}^t = \sqrt{[\mu_{ij}^t]^2 + [\nu_{ij}^t]} .
\]  (17)

For the remaining parameters $s_{ij}^{1:T}$, $J_{ij}^{1:T}$, $\lambda$, $\gamma$, and $\alpha$, the corresponding prior and likelihood are within the conjugate-exponential family, and hence, we omit the detailed derivations of their variational distributions. We summarize the VB algorithm in Algorithm 1. The resulting computational complexity of the proposed algorithm is $O(TP^3)$. As the complexity scales linearly in $T$, the model is applicable to problems with large $T$.

4. EXPERIMENTAL RESULTS

In this section, we validate the proposed model via both synthetic data and real data. Particularly, we benchmark the proposed model (referred to as VB-TVGM) with 1) the frequentist method for learning time-varying graphical models (referred to as OPT-TVGM) [9, 12], 2) the graphical lasso (i.e., glasso) for learning sparse graphical models from i.i.d. data [2]. The penalty parameters in the latter two methods are selected by AIC [10] and stability selection [27] respectively.

4.1. Synthetic Data

We simulate synthetic Gaussian distributed data from both relatively smoothly and abruptly changing precision matrix. The dimension of the data is $P$ and the sample size is $T$. For both scenarios, we first randomly partition all off-diagonal elements into two sets: 10% of non-zeros and 90% of zeros. Next, in the first case, we randomly select $n$ elements from each set. For the $n$ elements chosen from the non-zero set, we gradually shrink them to 0 as a linear function of $t$. Similarly, for the $n$ elements selected from the zero set, we increase them from zero to a rate linear in $t$. On the other hand, under the second scenario, the precision matrix only changes at $t = t_p, 2t_p, \cdots$, where $t_p$ is a predefined period. At every $t_p$ time step, we randomly choose $n$ elements from the non-zero set and set them to zero, while picking $n$ elements from the zero set and set them to non-zero. In our simulations, $T = 3000$, $P = 20$, $n$ equals 9 and 4 respectively in the first and second scenario, and $t_p = 500$.

For both cases, we compare the performance of the three models in terms of accuracy of learning the graphical models, model fitting and computational time. More specifically, to evaluate accuracy of graph model estimation, we consider four criteria, including precision, recall, F1-score as well as the normalized mean squared error (NMSE) between the true and estimated precision matrices. Precision is defined as the proportion of correctly estimated edges to all the edges in the
estimated graph; recall is defined as the proportion of correctly estimated edges to all the edges the true graph; $F_1$-score is defined as 2-precision-recall/(precision+recall), which is a weighted average of the precision and recall. In order to assess model fitting, we evaluate the negative log-likelihood (negLogLLH), the number of parameters (Pm No.) in the model, and the AIC score. The results averaged over 100 data sets in each scenario are listed in Table 1.

As can be seen from the table, OPT-TVGM is unable to reliably recover the true graphical model, although it introduces the largest number of parameters. The lowest NegLogLLH further suggests that this approach overfits the data. Indeed, as reported in [14], graphical model selection via AIC typically generates over-dense graphs. It is therefore imperative to find a proper method to select the penalty parameters, and this again highlights the significance of our work. In addition, OPT-TVGM is very time-consuming, and can be prohibitive to large-scale data in practice. On the other hand, the performance of glasso for model fitting is the worst among the three models, since it fails to capture the temporal variations in $K^t$. Furthermore, by comparing the results of two case studies, we can tell that this issue is exacerbated when $K^t$ changes more drastically. In contrast, the proposed VB-TVGM successfully strikes a balance between data fitting and graph recovery. Moreover, the model is free of tuning and the computational time is several magnitudes smaller than that of OPT-TVGM.

4.2 Scalp EEG of AD Patients

In this section, we consider the problem of inferring functional brain networks from scalp EEG recordings. Specifically, we analyze two data sets. The first one contains 22 patients with mild cognitive impairment (MCI, a.k.a. predementia) and 38 healthy control subjects [28]. The second one consists of 17 patients with mild AD (i.e., the first stage of AD) and 24 control subjects [29]. Although AD cannot be cured, current symptoms-delaying medications are proven to be more effective at early stages of AD [28]. On the other hand, scalp EEG recording systems are inexpensive and potentially mobile, thus making it a useful tool to screen a large population for the risk of AD.

As explained in Section 2.3, we first perform fast Fourier transform on all channels of EEG signals to obtain $f^\omega$. $K^\omega$ is then inferred from $f^\omega$ by applying the proposed VB-TVGM. After obtaining $K^\omega$ for all frequencies $\omega$, we further consider several frequency ranges: $4 – 8$Hz, $8 – 12$Hz, and $12 – 30$Hz, as suggested by previous works on the same data sets [28, 29].

Fig. 2: Boxplots for the number of edges resulting from VB-TVGM.

For each frequency band, we infer the corresponding graphical models by finding the common zero patterns of all $K^\omega$ in this band. Finally, we count the number of edges in the graphical models, which can be regarded as a measure of synchrony between different EEG channels. We observe that graphical models in $8 – 12$Hz can best distinguish between patients and controls for the MCI data, while $4 – 8$Hz for the mild AD data. We depict in Fig. 2 the boxplots of the number of edges in the graphical models for both patients and control subjects. Clearly, the graphical models for patients are more sparse than that for healthy people, and this phenomenon becomes more pronounced for Mild AD patients. Such findings are consistent with the loss of synchrony within the EEG signals for AD patients as reported in the literature [28, 29]. We further conduct Mann-Whitney test on the number of edges in the graphical models from the EEG of patients and healthy controls. The resulting p-values for the two data sets are respectively $3.53 \times 10^{-2}$ and $2.09 \times 10^{-4}$, which are statistically significant. As a comparison, we filter EEG signals with a bandpass filter (i.e., $8 – 12$Hz for MCI and $4 – 8$Hz for Mild AD), and utilize glasso to learn graphical models in time domain. The resulting p-values are 0.15 for the MCI data and 0.82 for the Mild AD data. Obviously, the proposed model can more accurately describe the perturbations in the EEG synchrony for MCI and mild AD patients.

5. CONCLUSIONS

In this paper, we formulate the problem of estimating time-varying graphical models from a Bayesian perspective. A variational Bayes algorithm is then developed to learn the model without tuning. We further apply the proposed model to learn graphical models between multiple time series in fre-
frequency domain. Numerical results from EEG data of MCI and AD patients show that the proposed model may help diagnose AD from scalp EEG at an early stage.
